Abstract

Study Objective: Quantify cervical spine range of motion during laryngoscopy via either direct laryngoscopy with a Miller blade or via video laryngoscopy with a CMAC system.

Design: Prospective case series

Setting: Interventional radiology suite at an academic medical center

Patients: Five adults requiring general anesthesia with tracheal intubation to facilitate interventional radiology procedures

Interventions: Fluoroscopic imaging of cervical spine anatomy prior to induction of general anesthesia and then during both direct laryngoscopy and video laryngoscopy

Measurements: Quantification of angles between skull base and prespecified cervical vertebrae and between the first cervical vertebrae and lower prespecified cervical vertebrae. These groups of measurement either do or do not account for movement of the atlanto-occipital joint, respectively.

Main Results: There was a tendency toward reduced cervical extension both relative to skull base and intrinsically within the cervical spine during laryngoscopy with the CMAC video laryngoscope as compared to direct laryngoscopy with a Miller blade.

Conclusions: We describe a novel technique to quantify cervical motion during laryngoscopy. Laryngoscopy with a CMAC video laryngoscope may reduce cervical extension as compared to direct laryngoscopy with a Miller blade. Video laryngoscopy may attenuate cervical extension during laryngoscopy, an effect that can be useful in patients with cervical spine disease or instability.

Keywords: Laryngoscopy; Airway; Intubation; Video laryngoscopy, Direct Laryngoscopy; Fluoroscopy.

Introduction

The degree of mobilization of the cervical spine (CS) during orotracheal intubation maneuvers (OTI) is of great importance during airway management in patients with pathology or instability of the CS, such as in those with cervical spinal cord trauma (CT) or other chronic diseases [1]. A reduction in CS movement during OTI is beneficial for these patients because undesirable mobilization can create or worsen a neurological injury [2]. Moreover, patients with cervical instability and acute cardiovascular or airway compromise may require a rapid intubation which should be made in the fewest attempts possible while minimizing cervical mobilization (CM) as much as possible [3]. Patients with other spinal cord diseases also benefit from a reduction in CS motion during direct laryngoscopy (DL), because this decreases the possibility of nerve and vascular structure compression due to vertebral displacement.

Video-laryngoscopy (VL) has been evaluated in different clinical context showing high success rates for OTI with [4–6] or without predictors of difficult airway [7]. VL in patients with cervical pathology can match or exceed the success rate of direct laryngoscopy, using comparable times and possibly reducing extension of the CS [8]. The difference in CS mobilization angles during
OTI via DL have not been compared to those encountered with the Cmac video laryngoscope (Karl Storz, Tuttlingen - Germany). The aim of the study is to compare the range of motion of the CS during OTI with the CMAC video laryngoscope using a D-Blade blade against DL with a Miller blade in healthy patients using fluoroscopy.

Materials and Methods

The institutional ethics committee approved the study protocol. Five patients were included without randomization, all > 18 years of age without cervical pathology and without predictors for a difficult airway. Patients were all previously scheduled for radiologic procedures distant to the CS, requiring the use of fluoroscopy, and requiring general anesthesia and OTI. Patients signed their approval form for the inclusion in the study by signing an informed consent.

Anesthetic Management

All patients were assessed in a pre-anesthetic consultation. They underwent conventional anesthesia according to hospital protocol in an interventional radiology suite. Induction of general anesthesia was conducted with a combination of propofol and remifentanil. Rocuronium was administered to facilitate laryngoscopy and OTI. Maintenance of general anesthesia consisted of sevoflurane and remifentanil with additional doses of rocuronium administered to maintain muscle relaxation. Basic monitoring was performed with electrocardiography, noninvasive blood pressure, pulse oxymetry, capnography, body temperature and a gas analyzer. Patients then underwent their radiologic procedure. Once the procedure ended, each patient was allowed to emerge from general anesthesia, the tracheal tube was removed when appropriate, and the patient was then transferred to the post anesthetic care unit.

Laryngoscopy and Comparison of Cervical Motion

For each patient, a baseline fluoroscopic image of the lateral CS was obtained with the neck in the neutral position prior to induction of general anesthesia. All images were obtained with a digital angiograph Philips Integris Allura Xper FD20 (Philips Medical Systems DMC GmbH, Hamburg, Germany). All laryngoscopies were conducted with the standard technique by the same trained anesthesiologist. Following induction of general anesthesia and complete muscle relaxation, a second fluoroscopic image of the lateral CS was obtained during DL with a number 2 Miller blade and a conventional laryngoscope with an occipital support in place. Finally, laryngoscopy was performed with a CMAC video laryngoscope and a D-Blade without occipital support during which a third fluoroscopic image of the lateral CS was obtained. Normal oxygenation, blood pressure, and body temperature were ensured throughout the whole process. At this time, the patient was intubated using a guide stylet and the scheduled surgical procedure commenced.

Quantification of Cervical Mobilization

Five lines were constructed and used for the measurements of CS mobility as illustrated in Figure 1:

- Line 1, between the occipital base to the floor of the "sella turcica" (base of the skull).
- Line 2, between the lower edge of the anterior arch of C1 to the lower edge of the spinous process of C1.
- Line 3, between the lower edge of the vertebral body of C2 to the lower edge of spinous process of C2.
- Line 4, between the bottom edge of the vertebral body C3 to the lower edge of the spinous process of C3.
- Line 5, between the bottom edge of the vertebral body of C5 to the lower edge of the spinous process of C5.

To quantify mobility of the neck and cervical spine, seven angles were determined via intersections of the lines defined above. The angle between Line 1 and Line 2 corresponded to movement at the occipito-atlantal joint only. The angles between Line 1 and either Line 3, Line 4, or Line 5 corresponded to movement at the occipito-atlantal joint as well as within the cervical spine. The angle between Line 2 and either Line 3, Line 4, or Line 5 corresponded to motion only intrinsically within the cervical spinal

Figure 1. Anatomic Characterization of the Five Lines used to Assess Mobility of the Cervical Spine during Laryngoscopy.
vertebrae. Smaller angles indicated less extension integrated over the corresponding vertebral segments.

To quantify the degree of mobilization of laryngeal structures, the minimum distance between the tip of each laryngoscope and the closest point of the most anterior portion of the cervical spine was determined.

All images and measurements were performed by neuro-radiologists.

**Data Analysis**

Given the small sample size, a formal statistical analysis was not feasible. Data are reported in summary format. In addition, each angle obtained during laryngoscopy was subtracted from the angle determined in the neutral position for each patient. Medians and ranges were reported for each of the differences in angles.

**Results**

Five patients participated in the study of whom 2 were male (40%). Median age was 57 years, with a range from 34 years to 74 years.

The degrees of angulation were measured in the cervical segments in the neutral head position, when viewing the glottis with direct laryngoscopy with Miller blade, and during video laryngoscopy with CMAC with a D blade. These data are summarized in Table 1. OTI maneuvers with both the Miller blade and the CMAC system increased all angles compared to those obtained in the neutral position and occurred with respect to the skull base and intrinsically within the cervical spine. The increase in most angles were greater with DL than with the use of the CMAC system.

Each angle obtained during laryngoscopy with both Miller blade and CMAC device were subtracted from the corresponding angle obtained with the patient in the neutral position and these data are summarized in Table 2. There was a tendency toward greater neck extension during DL with a Miller blade as compared to that obtained during VL with the CMAC system both in comparison to skull base and intrinsically with the cervical spine.

In all five patients, a greater anterior displacement of airway structures was obtained with the CMAC VL compared to the Miller laryngoscope as determined by a greater distance achieved between the tip of the laryngoscope and closest and most anterior portion of the cervical spine as shown in Table 3.

**Discussion**

To our knowledge, the difference in CM during DL has not been previously studied with a Miller blade compared to VL. CMAC with D-Blade blade in healthy patients, as measured by fluoroscopy. Previous studies evaluated the cervical mobilization by fluoroscopy during laryngoscopy with Macintosh blade [9, 10]. In these studies the joints C1 and C2 showed the greatest range of motion relative to the occiput.

Our study suggested that the extension of the CS was higher with DL with a Miller blade that when CMAC VL was used. This finding was observed in the mobilization of all joints evaluated from

The study findings support the use of CMAC with a D-Blade over direct laryngoscopy in patients with cervical pathology, since the reduction in CM is a protective factor against the risk of exacerbating a spinal cord injury [3].

In patients with CT, an OTI rapid sequence accompanied by manual inline stabilization is recommended for securing the airway in emergency situations [11]. Manual in line stabilization reduces the possibility of moving the spine during DL, but it may hinder laryngoscopy [12, 13]. Although manual inline stabilization can also be used with VL, its potential to hinder OTI is much lower because it does not require alignment of the laryngeal, pharyngeal and oral axes [7].

Several design features improve the glottal CMAC visualization [16]. The blade is thinner than traditional blades (maximum 14 mm) with a beveled edge which reduces the chance of oral or dental trauma. The optical device includes a chip that produces an image of 320x240 pixels from a lens located in the distal third of the blade and creates a viewing angle of 80 degrees. It also has a high power light-emitting diode and an anti-fogging system [15]. This design magnifies the image and extends in front of the lens in 60 degrees in the longitudinal direction and 80 degrees crosswise offering an advantage for patients with an anterior located larynx [17, 18].

The CMAC VL device allows the retraction of periglottic soft tissue without aligning the laryngeal, pharyngeal and oral axes as illustrated in Figure 2 [19], which happens with conventional laryngoscopes (see Figure 3). Clinical studies have compared the display quality between different VL; taking into account light intensity, contrast between anatomical structures and view field [20]; finding clinical and design advantages in favor of CMAC that could explain the high efficiency in patients with predictors of a difficult airway [21].

The 40º curvature of the blade D-Blade contrast with 18º of traditional McIntosh blade [8], favoring a more anterior location of the tip of the blade with an anterior displacement of the vallecula [22]. This creates a distension of the supra-glottis structures below the blade, visually separating the glottis and facilitating the differentiation, increasing the success rate. This is illustrated in Figure 3.

We were also able to demonstrate that, despite less cervical spine extension, laryngoscopy with the CMAC VL was able to provide great anterior displacement of the anterior supralaryngeal structures and a wider field of view than DL with a Miller blade. Specifically, in each case, there was a largely distance between the CS and the tip of the laryngoscope. See the Figures 2 and 3 to compare.

The main limitation of this study is its small sample value. This pilot study may be complemented by a study of greater size and statistical power. Our institution underwent a practice change that limited recruitment of more patients for this series. The Miller straight blade was used in this work as comparative to Cmac. This decision was based on the fact that in our hospital the DL Miller blade is used routinely. Previous studies have shown that differences in CM valued by fluoroscopy were comparable during a DL with Miller, Macintosh or McCoy blades [23]. We believe that our results can be extrapolated to the use of Macintosh blades. Finally, the lack of monitoring of the laryngoscopy technician may generate observer bias, and a tendency to overestimation of the
beneficial effect of video laryngoscope.

Conclusions

With the use of fluoroscopy, we were able to demonstrate that laryngoscopy with a CMAC VL provided a wider separation of anterior airway structures and the cervical spine despite less intrinsic and extrinsic CS motion during laryngoscopy compared to laryngoscopy with a Miller laryngoscope. This, in patients with known or presumed cervical spine injuries, the use of the CMAC VL can limit CM during airway management without sacrificing airway structure displacement during laryngoscopy.
