Lymphocyte Subset (CD3, CD4 and CD8 Cells) and their Ratios in HIV patients on Highly Active Antiretroviral Therapy (HAART) and HAART Naïve Patients

Background: Lymphocytes form part of the blood cells involved in the fight against infection in the immune system. These cells are mostly implicated in the pathogenesis of HIV/AIDS.

Objective: This study sought to determine the lymphocyte differentials in seropositive HIV patients on HAART and HAART naïve.

Materials and Methods: This was a hospital-based, case control study conducted among 150 participants. HIV patients' on HAART (n=50) and HAART naïve HIV (n=50) patients and the control group (n=50) was HIV Seronegative individuals. Venous blood was drawn from each of the participant into K3 EDTA tubes. Becton Dickinson (BD) FACS Count system was used to determine the lymphocyte differentials (CD3, CD4 and CD8).

Results: The study observed an average CD3 of 1867 ± 99.72 cells/mm³, 1639 ± 96.56 cells/mm³ and 1755 ± 139.3 cells/mm³ in the control, on HAART and HAART naïve groups respectively, CD4 of 1084 ± 55.40 cells/mm³, 498.5 ± 43.85 cells/mm³, and 506.7 ± 60.58 cells/mm³ in the control, on HAART and HAART naïve groups respectively and CD8 of 662.0 ± 45.84 cells/mm³, 1091 ± 74.81 cells/mm³ and 1210 ± 125.3 cells/mm³ in the control, on HAART and HAART naïve groups respectively.

Conclusion: The pathogenic effect of HIV virus resulted in significantly low mean levels of CD4, CD8, CD4/CD3 and CD4/CD8 ratio among on HAART and HAART naïve patients compared to control group.

Introduction

Lymphocytes form part of the blood cells involved in the fight against infection in the immune system. They function in the adaptive immunity where the B-lymphocytes function under the humoral immunity and the T-lymphocytes function under the cell-mediated immunity which is involve in the defence against intracellular microbes. The latter is further classified as CD4+ and CD8+ with the CD standing for Cluster of Differentiation. These are the cells which are mostly implicated in the pathogenesis of HIV/AIDS. However, diverse effect is observed following their activation. The presence of HIV in the host cell induces response which culminates into immune activation. Immune activation though important for host in wading effective immune response against HIV, its repeated occurrence creates an oxides environment for the virus to replicate [1]. Active molecular and cellular processes are among the several events that characterize immune activation in HIV patient.
During the early stage of HIV infection a lot of people initiate an effective immune response but it becomes ineffective over time. CD4 and CD8 T cells form the pillar of cellular response while humoral response involves the antibody production and its related activities [2]. CD8 T cells exercise its cytotoxic effect on the virus as well as secrete some chemokines during the primary stage of HIV infection. Some HIV patient are able to maintain high level of CD8+ specific T cell which control viral replication but it falls after infection in most patients. CD8 T cells can therefore be used to ascertain pathogenesis in HIV infected persons. Clinical studies conducted by Golgi and colleagues concluded that excessive immune activation leads to immune dysfunction in chronic HIV patients. The findings showed that CD38 a maker of CD8 T cell and HLA-DR expression negatively correlate better with the worse condition of HIV infected persons than viral load [3-5]. So as CD4+ T-cell numbers decrease in HIV condition, HLA-DR+ and CD38+ CD8+ T lymphocytes rather appreciate in numbers [5]. Further studies has also established that viral load cannot separately determine the rate of progression to AIDS, and that immune activation better reflects variations in CD4+ T-cell stronger and independent of viral load [6-9].

The survival rate of HIV patient is closely related to the levels of activated CD8+ T cells than CD4+ T cells or viral load [5] and high viremia in some HIV patient is not an indication of HIV pathogenesis [10, 11]. Immune activation is highly related to high incidence of diseases and death in successfully HAART-treated patients with undetectable viremia [12]. Certain stage of infection records complete absence CD4+ T cells both in the lymphoid and circulation sites. At this stage the infected HIV individual starts experiencing AIDS condition [13]. AIDS ushers the gradual breakdown of the immune status as a result of the reduced level of CD4 T cell and high levels of inflammatory cytokines which suppresses other immune cells from replenishing lost ones. Contrarily to CD4+ T cell, CD8+ T-cell rather increase in their numbers due to the expansion of memory CD8+ T cells usually HIV-reactive cells during the early stage of HIV infection. Expansion of CD8+ T cell may reduce at the later stage of HIV infection. Although naïve CD8+ T cell may decrease during the beginning of HIV infection, absolute count of CD8 T cells only declines when HIV disease progresses. This therefore makes it expedient to get credible CD4 count results in order to estimate immunity build up and properly manage the health of persons infected with HIV [14]. It is important that clinicians request for CD4 count to be done for HIV infected patients every 3-6 months, so that those with low levels of CD4 count are placed on antiretroviral therapy. Presentation of low absolute CD4 counts and the perturbed high level of cytokines indicates break down of the immune system of HIV patient.

Materials and Methods

This was a hospital-based, case control study conducted from June to November 2014 in the Komfo Anoyke Teaching Hospital (KATH), Kumasi, Ghana. 150 participants in all were recruited for this study. Hundred participants were recruited from the HIV clinic at KATH out of which 50 were on ART and the other 50 participants were treatment naïve. The 50 control group was selected from client visiting the blood bank unit of KATH to undertake the study at the serology unit of the Komfo Anoyke Teaching Hospital.

Sample Collection and Determination of Lymphocyte Differentials

3 ml of venous blood was drawn from each of the participant by venepuncture into K3 EDTA vacutainer tube. The immunological markers that were determined were absolute cell counts of CD4, CD8 and CD3 T lymphocytes in unlysed whole blood. The CD4, CD8 and CD3 T lymphocytes counts were determined using the Becton Dickinson (BD) FACS Count system (Becton, Dickinson and Company, California, USA). The CD4 count reagent was inverted up and down for 10 sec in order to suspend the bead and then uncorked with the coring station. After which 50μl of the sample (whole blood) was added to the corresponding tube. The mixture was vortexed and incubated at room temperature in the dark for 60-120 minutes. 50μl of the fixative solution was added, caped and incubated for 15 mins. It was then immediately analyzed on the FACS count instrument after vortexing upside down for 5 sec. The in-built software then analyze and quantifies the CD4+ lymphocyte, CD8+ lymphocytes, CD4+/ CD8+ ratio and the absolute CD3 count of each sample.

Statistical Analysis

The data was analysed using the Statistical Package for Social Scientist (SPSS) Statistical Software (version 17.0, SPSS Inc., Chicago, IL, USA). For all statistical comparisons, the level of significance was set at p<0.05.

Results

Demographic Characteristics of Study Population

The mean age of the HIV patients (38.57 ± 1.13 for those on treatment and 37.25 ± 1.19 for treatment naïve) were significantly higher (P<0.0001) respectively than that of the controls (22.35 ± 1.03). The female participants (42 for those on treatment and 36 for the treatment naïve) far outnumber the male participants (8 for on-treatment and 14 for treatment naïve). However for the controls the number of males (37) was almost three times the number of females (13).
Lymphocyte Subset Analysis for Study Population

Mean levels of CD8, CD4, and the ratio of CD4/CD8 were significantly lower among treatment and treatment naïve HIV infected participants compared to control (p<0.0001). Moreover, the ratio of CD4/CD3 was significantly lower among treatment and treatment naïve HIV infected participants compared to control (p<0.0001) (Table 2) but difference between treatment and treatment naïve was not significant.

Discussion

The study observed a significant decrease of CD4 T cell in seropositive HIV studied group compared to seronegative group (Table 1.0). Generally CD4 count in HIV patient have been observed to decline as the disease progresses [1,2] and is a vascular risk factor among HIV-infected individuals [15]. The increased rates of apoptosis within blood lymphocyte subsets in HIV positive individuals [16] could contribute to lower lymphocyte levels. Secondly, the interactions between the virus g120 and the CD4 T cell of the host cell induce by IFN can result apoptosis of the host cell due to the deleterious effect of the virus activity on the CD4+ T cell [17]. Thirdly the thymosupressive effect of pro-inflammatory cytokines (IL-6) [18] can affect the thymus output. This leads to fibrosis of the lymphatic tissue damaging the architecture and preventing normal T cell homeostasis [18,19]. Due to this there is a reduction in the number of new cell that is churns out by the thymus in seropositive HIV patient [13]. The ability of HIV infected patient in replacing lost T cells becomes compromised. As the naïve T cell pool are not been replenished, with time there will not be any T cell to supplant the old CD8 and CD4 T cell when they die out. At such situation attack by new strain of the virus receive less resistance from the CD8 T and CD4 T cell when they die out. At such situation attack by new strain of the virus receive less resistance from the CD8 T

There was no significant difference between the CD4+ T cell of the On-treatment and treatment naïve group probably because, effective HAART regimes results in similar decay of plasma HIV-RNA [20].

There was a significant high level of CD8+ T cell in seropositive HIV compared to control group (Table 1.0). In HIV infected individuals CD8+subset in the blood from site such as the lung are unable to migrate into high endothelia venule-containing lymphoid tissue due to insufficient expression L-selectin homing receptor(s) or an inability to transduce G-protein-associated signals leading to its accumulation in the peripheral blood. CD8+ T cell are also known to expand more extensively than CD4+ T cells during immune response. This might have accounted for the overall increase in CD8+ T cell in HIV infected individual. As the blood CD4+ T cells declines, CD8+ T cell levels are either maintained or increased, this will therefore result in CD4/CD8 ratio decreasing in order to maintain homeostatic mechanisms. This trend was consistent with this study results (Table 1) which indicates a significant decrease of CD4/CD8 ratios of the seropositive HIV group compared to the control group. However, the ratio of CD4/CD3 was significantly lower among treatment and treatment naïve HIV infected participants compared to control. The low level of CD4/CD3 exhibit a steady progression of the HIV infection [5,7] and is used to monitor some forms of immunodeficiency [4]. The association between low CD4+ T-cell count may possibly be explained by chronic inflammation in immunosuppressed HIV-infected individuals [21]. Meanwhile there was a significant positive correlation between CD8 T cell and CD3 T cells and between the ratio of CD4/CD8 and the ratio of CD4/CD3. A significant and negative correlation of CD8 T cell was observed with the ratio of CD4/CD8 and CD4/CD3 in all the studied participants.

Conclusion

From this present study, it was evident that HIV infection is more prevalent among females than males. This present study also established that the pathogenic effect of HIV virus resulted in significantly low mean levels of CD4, CD8, CD4/CD3 and CD4/CD8 ratio among on HAART and HAART naïve patients compared to control group (p< 0.0001).
